Interatomic potential or force-field plays a vital role in simulating materials. Empirical potentials like the embedded atom method (EAM) and its variant angular-dependent potential (ADP) have proven successful in modeling many metals qualitatively. In the past few years, machine learning has become the key approach for modeling interatomic interactions. Powered by big data and efficient optimizers, machine learning interatomic potentials can generally approximate to the first-principle accuracy. In this work, we successfully developed a route to express EAM and ADP within machine learning framework in highly-vectorizable form and further enhanced the potentials with physical constraints. Machine learning can significantly boost their performances with few training data. For energy and force predictions, machine learned EAM and ADP can be almost as accurate as the spectral neighbor analysis potential (SNAP) on the fcc Ni, bcc Mo and Mo-Ni alloy systems, while the molecular dynamics simulations performed by our potentials are nearly 1000 times faster. Machine learned EAM and ADP can also give first-principle accuracy key material properties, such as elastic constants, melting temperatures and surface energies. Our results suggest a new and systematic route for developing machine learning interatomic potentials. All the new algorithms have been implemented in our program TensorAlloy.

## I. INTRODUCTION

Atomistic modeling plays a vital role in materials science. *Ab initio* calculation or force-field based molecular dynamics simulation (MD) are effective ways to study, understand or predict chemical and physical properties of materials. *ab initio* approaches are generally much more precise but they are rarely used on large-scale metallic systems due to their extremely-high computation expenses. Physical model based empirical potential (force-field), such as the embedded-atom method (EAM) [1–5], modified embedded-atom method (MEAM) [6–9], bond-order potential (BoP) [10–13], or angular-dependent potential (ADP) [14–18], still plays the major role in long-time simulations and these empirical methods can achieve reasonable accuracy with much lower computation costs. Empirical potentials generally have very few learnable parameters and both microscopic observables (energy, forces, virial, etc.) and macroscopic observables (melting point, surface energy, etc.) can be used to tune these parameters. Finding optimal parameters of empirical potentials is always a challenging task. Global optimization (GO) approaches (Basin-Hopping [19, 20], genetic algorithm [21, 22], etc) are traditionally used to find the best possible parameters. However, the gradients of the losses with respect to model parameters are difficult or even impossible to calculate. Hence, global optimizations are generally not that effective.

In the last decade, machine learning (ML) has become one of the hottest topics in many research areas. In the materials science, researchers have made great efforts on developing ML models to describe atomic interactions. Such ML models are considered as machine

learning interaction potentials (MLIPs). Until now, hundreds of MLIPs have been proposed. Among them, the symmetry-function based atomistic neural network (ANN) model, published by Parinello and Behler in 2007 [23–27], is still the most popular choice in modeling metallic interactions [28–30]. The smooth overlap atomic positions descriptor based gaussian approximation potential (SOAP-GAP) [31–34], developed by Bartók et al, can give extremely accurate prediction results, although it's a bit computationally expensive. Recently, Thompson and co-workers proposed another quantum-accurate MLIP named the spectral neighbor analysis potential (SNAP) [35] and it has been proven working on a broad range of metals and alloys [36–38].

In many cases, MLIPs can easily outperform state-of-art empirical potentials. Compared with empirical potentials, MLIPs generally have orders of magnitudes more model parameters. The redundant parameter space greatly reduces the difficulty of fitting complicated potential energy surfaces. But, to effectively train a MLIP and avoid overfitting, a large high-quality (versatile) training dataset is probably needed. However, MLIPs **can really** take advantages of "big data" for two reasons. First, MLIPs typically only have *basic* or *simple* arithmetic operations. Thus, MLIPs can be implemented within modern deep learning frameworks (TensorFlow [39], PyTorch [40], etc) so that the gradients of the total loss with respect to fitting parameters can be obtained with the backpropagation algorithm automatically and efficiently. Second, MLIPs are mostly vectorizable. Hence, GPUs can be utilized to significantly accelerate training and using of MLIPs.

However, MLIPs also have challenges. The large parameter space and lack of physical background makes the "big data" a requisite. The cost of dataset is non-negligible. Besides, even "big data" can only cover a small portion of real physical environments (tempera-

\* lindeye0716@163.com

† song\_haifeng@iapcm.ac.cn

ture, external pressure, etc). Outside the training zone, the performances of MILPs may not that stable. For long-time molecular dynamics (MD) simulations of large-scale ( $10^5$  or more) systems, computation efficiency also becomes a major concern. Recent benchmark tests [41] suggest that MILPs are still too expensive. At present, most MLIPs are used to examine small to medium ( $10^3$  to  $10^4$ ) systems [28–30, 34, 37].

In this work, instead of designing new atomic descriptors, we chose a new route to develop MLIP: combining machine learning with empirical potentials. We successfully implemented EAM and its variant ADP within TensorFlow so that machine learning approaches can be used directly to tune EAM and ADP potentials. Our results suggest ML-EAM or ML-ADP can be as precise as the SNAP machine learning method.

This paper is organized as follows. Section II describes the theoretical background of this work, including the formalism of the embedded atom method and algorithms of the machine learned EAM. Section III describes the implementation details. Section IV summarizes the results of ML-EAM and ML-ADP. Further discussions are given in section IV C.

All the new algorithms have been implemented in our program TensorAlloy [42].

## II. METHOD

### A. Theory

In the original EAM formalism [1], the total energy,  $E^{total}$ , is the sum of atomic energies:

$$\begin{aligned} E^{total} &= \sum_i^N E_i \\ &= \sum_i^N F_a(\rho_i) + \frac{1}{2} \sum_i^N \sum_{j \neq i}^{r_{ij} < r_c} \phi_{ab}(r_{ij}) \end{aligned} \quad (1)$$

where  $r_c$  is the cutoff radius,  $a$  and  $b$  represents species of atoms  $i$  and  $j$ ,  $\phi_{ab}(r_{ij})$  is energy of the pairwise interaction between  $i$  and  $j$ ,  $F_a(\rho_i)$  is the embedding energy and  $\rho_i$  is the local electron density of atom  $i$ .  $\rho_i$  can be calculated with the following equation:

$$\rho_i = \sum_j^{r_{ij} < r_c} \rho_b(r_{ij}) \quad (2)$$

where  $\rho_b$  is the electron density function of specie  $b$ .  $F$ ,  $\rho$  and  $\phi$  can be either parameterized functions or cubic splines.

The original EAM does not include angular-dependent interactions. To fix this problem, Baskes modified the original EAM and got MEAM (modified embedded-atom method) [6], Lenosky proposed an alternative spline-based interpretation of MEAM [43] while Mishin developed

the angular-dependent potential (ADP) [14–17, 44]. The ADP formalism introduces three additional terms to the total energy:

$$\begin{aligned} E^{total} &= E^{EAM} \\ &+ \frac{1}{2} \sum_i \sum_{\alpha} (\mu_i^{\alpha})^2 \\ &+ \frac{1}{2} \sum_i \sum_{\alpha} \sum_{\beta} (\lambda_i^{\alpha\beta})^2 \\ &- \frac{1}{6} \sum_i \nu_i^2 \end{aligned} \quad (3)$$

These terms represent non-central bonding contributions and they can be computed with the following equations:

$$\mu_i^{\alpha} = \sum_{j \neq i} \mu_{ab}(r_{ij}) r_{ij}^{\alpha} \quad (4)$$

$$\lambda_i^{\alpha\beta} = \sum_{j \neq i} \omega_{ab}(r_{ij}) r_{ij}^{\alpha} r_{ij}^{\beta} \quad (5)$$

$$\nu_i = \sum_{\alpha} \lambda_i^{\alpha\alpha} \quad (6)$$

where  $\mu_{ab}(r)$  and  $\omega_{ab}(r)$  can be viewed as measures of the strengths of dipole and quadrupole interactions.

### B. Transformation

To integrate EAM/ADP with machine learning strategy, the original total energy expression (Equation 1) must be transformed to a vectorizable form. Without loss of generality, we take the binary alloy, AB, to demonstrate how to do the transformation.

Suppose the cutoff radius  $r_c$  is fixed, the energy of atom  $i$  of specie  $A$  can be calculated with the following expanded equation:

$$\begin{aligned} E_i^A &= \frac{1}{2} \sum_{j \neq i}^{N_i^{AA}} \phi_{AA}(r_{ij}) + \frac{1}{2} \sum_{j \neq i}^{N_i^{AB}} \phi_{AB}(r_{ij}) \\ &+ F_A \left( \sum_{j \neq i}^{N_i^{AA}} \rho_A(r_{ij}) + \sum_{j \neq i}^{N_i^{AB}} \rho_B(r_{ij}) \right) \end{aligned} \quad (7)$$

where  $N_i^{AA}$  represents the number of A-type neighbors of atom  $i$  and  $N_i^{AB}$  represents the number of B-type neighbors. For atom  $j$  of specie  $B$ , we can also write a similar form.

$$\begin{aligned} E_j^B &= \frac{1}{2} \sum_{i \neq j}^{N_j^{BB}} \phi_{BB}(r_{ij}) + \frac{1}{2} \sum_{i \neq j}^{N_j^{BA}} \phi_{AB}(r_{ij}) \\ &+ F_B \left( \sum_{j \neq i}^{N_j^{BB}} \rho_B(r_{ij}) + \sum_{j \neq i}^{N_j^{BA}} \rho_A(r_{ij}) \right) \end{aligned} \quad (8)$$

When  $r_c$  is fixed,  $N_i^{AA}$ ,  $N_i^{AB}$ ,  $N_j^{BB}$  and  $N_j^{BA}$  are all constants and  $N_i^{nl}$  is the maximum of these numbers of structure  $i$ . Hence, we can pre-determine the maximum neighbor list size  $N^{nl}$ :

$$N^{nl} = \max(N_i^{nl}) \quad (9)$$

$N^{nl}$  is also a constant in the training phase because both the training dataset and  $r_c$  are fixed.

Next, assume  $H(x)$  represents the heaviside step function:

$$H(x) = \begin{cases} 1 & x > 0 \\ 0 & x \leq 0 \end{cases} \quad (10)$$

then the pairwise term can be transformed to:

$$\begin{aligned} \sum_{j \neq i}^{N_i^{AA}} \phi_{AA}(r_{ij}) &= \sum_{j \neq i}^{N_i^{AA}} \phi_{AA}(r_{ij}) \cdot 1 + \sum_{j \neq i}^{N^{nl} - N_i^{AA}} \phi_{AA}(0) \cdot 0 \\ &= \phi_{AA}(\vec{r}_i^{AA})^T H(\vec{r}_i^{AA}) \end{aligned} \quad (11)$$

where  $\vec{r}_i^{AA}$  is a  $N^{nl}$ -length column vector whose last  $N^{nl} - N_i^{AA}$  elements are zeros.

We can write Equation 7 in an equivalent expression:

$$\begin{aligned} E_i^A &= \frac{1}{2} (\phi_{AA}(\vec{r}_i^{AA})^T H(\vec{r}_i^{AA}) + \phi_{AB}(\vec{r}_i^{AB})^T H(\vec{r}_i^{AB})) \\ &\quad + F_A (\rho_{AA}(\vec{r}_i^{AA})^T H(\vec{r}_i^{AA}) + \rho_{AB}(\vec{r}_i^{AB})^T H(\vec{r}_i^{AB})) \end{aligned} \quad (12)$$

Here  $\vec{r}_i^{AB}$  is also a  $N^{nl}$ -length vector. For atom  $j$  of specie  $B$ , we can also derive its energy  $E_j^B$ :

$$\begin{aligned} E_j^B &= \frac{1}{2} (\phi_{BB}(\vec{r}_j^{BB})^T H(\vec{r}_j^{BB}) + \phi_{BA}(\vec{r}_j^{BA})^T H(\vec{r}_j^{BA})) \\ &\quad + F_B (\rho_{BB}(\vec{r}_j^{BB})^T H(\vec{r}_j^{BB}) + \rho_{BA}(\vec{r}_j^{BA})^T H(\vec{r}_j^{BA})) \end{aligned} \quad (13)$$

Since  $\vec{r}_i^{AA}$ ,  $\vec{r}_i^{AB}$ ,  $\vec{r}_i^{BB}$  and  $\vec{r}_i^{BA}$  all have the same length ( $N^{nl}$ ), we can use a (redundant) matrix,  $\mathbf{g}_i$ , to describe all neighbors of atom  $i$ :

$$\mathbf{g}_i = [\vec{r}_i^{AA} \quad \vec{r}_i^{AB} \quad \vec{r}_i^{BB} \quad \vec{r}_i^{BA}]^T \quad (14)$$

$\mathbf{g}_i$  is a  $4 \times N^{nl}$  matrix. If the specie of atom  $i$  is A, only the first two columns have non-zero values. Similarly, the last two columns will have non-zeros values if atom  $i$  is a B-type atom. In fact,  $\mathbf{g}_i$  can be viewed as the EAM descriptors for atom  $i$ . Hence, each structure can be expressed with a 3D matrix,  $\mathbf{G}$ , of shape  $N \times 4 \times N^{nl}$ .

During the training phase, the maximum appearances of element A and B in any structure ( $N_A^{\max}$  and  $N_B^{\max}$ ) are also constants. Thus, any  $\mathbf{G}$  can be expanded to a  $(N_A^{\max} + N_B^{\max}) \times 4 \times N^{nl}$  matrix  $\mathbf{G}'$  by zero-padding. In summary, arbitrary structure in the training dataset can be converted to a fixed-shape descriptor matrix  $\mathbf{G}'$ .

FIG. 1. Visualization of the descriptor matrix  $\mathbf{G}'$  of the binary AB system and  $N^{nl}$  is 7. Non-colored cells are padded zeros. (a) is a sample  $\mathbf{g}_i$  of A-type atom and (b) represents a B-type atom.

For the ADP formalism, the corresponding transformation is almost the same except that  $\mathbf{g}_i^{\text{adp}}$  should also include the  $\alpha, \beta, \gamma$  components of  $\vec{r}_i$ .

Fig 1 is the visualization of the descriptor matrix  $\mathbf{G}'$ .  $\mathbf{G}'$  has three axes: the neighbor axis, the interaction axis and the atom axis.  $N^{nl}$  is the maximum of the neighbor axis (in this case  $N^{nl} = 7$ ). For the binary AB system there are four types of interactions: AA, AB, BB and BA. (a) and (b) are samples of  $\mathbf{g}_i$  for A-type atoms and B-type atoms.

### C. Functions

In this work, we use the EAM potential published by Zhou, Johnson and Wadley (Zjw04) [45–47] as an example to validate our machine learning approach. Zjw04 is a quite popular EAM potential. In the Zjw04 potential, the electron density function has the following form:

$$\rho_b(r) = \frac{f_e \exp[-\beta(r/r_e - 1)]}{1 + (r/r_e - \lambda)^{20}} \quad (15)$$

where  $r_e$  is a constant equal to equilibrium spacing between nearest neighbors,  $f_e$ ,  $\beta$ ,  $\lambda$  are adjustable parameters. The pairwise potential between the same species can be computed with:

$$\phi_{aa}(r) = \frac{A \exp[-\alpha(r/r_e - 1)]}{1 + (r/r_e - \kappa)^{20}} - \frac{B \exp[-\beta(r/r_e - 1)]}{1 + (r/r_e - \lambda)^{20}} \quad (16)$$

where  $A$ ,  $B$ ,  $\alpha$  and  $\kappa$  are also trainable parameters,  $\beta$  and  $\kappa$  are used in Equation 15 already. For the pairwise interaction between two atoms of different species, the interpolation form is used:

$$\phi_{ab}(r) = \frac{1}{2} \left( \frac{\rho_b(r)}{\rho_a(r)} \phi_{aa}(r) + \frac{\rho_a(r)}{\rho_b(r)} \phi_{bb}(r) \right) \quad (17)$$

The embedding function has a more complicated form as it requires to fit a much wider range of electron density

values:

$$F(\rho) = \begin{cases} \sum_{i=0}^3 F_{ni} \left( \frac{\rho}{\rho_n} - 1 \right)^i & \rho < \rho_n \\ \sum_{i=0}^3 F_i \left( \frac{\rho}{\rho_e} - 1 \right)^i & \rho_n \leq \rho < \rho_0 \\ F_e \left[ 1 - \eta \ln \left( \frac{\rho}{\rho_s} \right) \right] \left( \frac{\rho}{\rho_s} \right)^\eta & \rho_0 \leq \rho \end{cases} \quad (18)$$

where  $F_{ni}$ ,  $F_i$ ,  $\rho_e$ ,  $\rho_s$ ,  $\eta$  and  $F_e$  are trainable parameters,  $\rho_n = 0.85\rho_e$  and  $\rho_0 = 1.15\rho_e$ . For each metal, there are 15 adjustable parameters. The original embedding potential is a stepwise function. Thus, the minimization requires some tricks to ensure its continuity. To make it simpler, we slightly modified Equation 18:

$$F(\rho) = c_1 \cdot \sum_{i=0}^3 F_{ni} \left( \frac{\rho}{\rho_n} - 1 \right)^i + c_2 \cdot \sum_{i=0}^3 F_i \left( \frac{\rho}{\rho_e} - 1 \right)^i + c_3 \cdot F_e \left[ 1 - \eta \ln \left( \frac{\rho}{\rho_s} \right) \right] \left( \frac{\rho}{\rho_s} \right)^\eta \quad (19)$$

$$c_1 = \frac{1}{1 + e^{-2(\rho_n - \rho)}} \quad (20)$$

$$c_3 = \frac{1}{1 + e^{-2(\rho - \rho_0)}} \quad (21)$$

$$c_2 = 1 - c_1 - c_3 \quad (22)$$

$c_1$  and  $c_3$  are just damping factors calculated by the sigmoid functions (Equations 20 and 21).

The dipole ( $\mu_{ab}$ ) and quadrupole ( $\lambda_{ab}$ ) functions have the same form (developed by Mishin [14]):

$$\mu_{ab}(r) = [d_1^{ab} \exp(-d_2^{ab}r) + d_3^{ab}] \psi \left( \frac{r - r_0}{r_h} \right) \quad (23)$$

$$\omega_{ab}(r) = [q_1^{ab} \exp(-q_2^{ab}r) + q_3^{ab}] \psi \left( \frac{r - r_0}{r_h} \right) \quad (24)$$

where  $d_i$ ,  $q_i$ ,  $r_0$  and  $r_h$  are trainable parameters and  $\psi(x)$  is a damping function:

$$\psi(x) = \begin{cases} 0 & x \geq 0 \\ \frac{x^4}{1+x^4} & x < 0 \end{cases} \quad (25)$$

#### D. Physical constraints

Physical constraints are quite common in fitting traditional empirical potentials. Physical constraints are typically static (cohesive energy, elastic constants, etc) collected from experiments and they can be very effective when training data is limited. For example, the cohesive energy, bulk modulus, vacancy formation energy and other constraints were used to develop the original Zjw04 potential. Mishin et al adopted the Rose universal equation of state to ensure the performances of his ADP potentials in the high pressure region. However, such

constraints are really rare in developing MILPs. One possible explanation may be these constraints are generally derived properties and implementing them in the loss function are technically difficult.

In this work, we successfully integrated two constraints into the total loss: the Rose equation of state (EOS) [48–50] constraint and the elastic tensor constraint. These two losses will be discussed later. The details of their implementations will be described in another paper.

The Rose constraint incorporates the universal equation of state (Rose et al) into the total loss function. The Mishin-modified equation

$$E^{\text{rose}}(x) = E_0 \left[ 1 + \alpha x + \beta \alpha^3 x^3 \frac{2x+3}{(x-1)^2} \right] e^{-\alpha x} \quad (26)$$

is used because the original form tends to underestimate energies under high pressures. In Equation 26,  $E_0$  is the energy of the equilibrium structure,  $x = a/a_0 - 1$  is the relative isotropic scaling factor ( $a$  is the lattice constant),  $\beta$  is a chosen parameter and

$$\alpha = \sqrt{\frac{9V_0 B}{E_0}} \quad (27)$$

where  $V_0$  is the equilibrium volume and  $B$  is the corresponding bulk modulus. The adoption of the Rose constraint guarantees the exact predictions of bulk modulus and the energy-volume curve. The loss of the Rose EOS constraint  $\mathbf{L}^{\text{Rose}}$  is measured as the 2-norm of the energy differences between  $E^{\text{rose}}(x)$  and their corresponding predicted  $E(x)$ :

$$\mathbf{L}^{\text{Rose}} = \sum_{\Omega} \sqrt{\sum_i (E(x_i) - E^{\text{rose}}(x_i))^2} \quad (28)$$

Here  $\Omega$  denotes all selected crystals. In this work, for each included crystal, we use the same choices of  $x$ , which determines the fitting region:  $x_i = x_0 + \Delta x \cdot i$ ,  $x_0 = -0.1$ ,  $N_t^{\text{max}} = 20$ ,  $\Delta x = 0.01$ . (-10% to +10% of the equilibrium volume). In this work,  $\beta^{\text{Ni}}$  is 0.005 and  $\beta^{\text{Mo}}$  is 0.008.

Elastic tensor is also a popular constraint for tuning empirical potentials but rarely used directly in optimizing MILPs. Shyue Ping Ong used this constraint in the outer loop (the global optimization based property-matching step) to find optimal parameters of SNAP potentials.

In this work, we find a straightforward way to use elastic tensor directly as a constraint. Given an equilibrium crystal structure, its elastic constant  $c_{ijkl}$  can be derived from  $E^{\text{total}}$  directly [51]:

$$V \cdot \epsilon = -\mathbf{F}^T \mathbf{R} + \left( \frac{\partial E^{\text{total}}}{\partial \mathbf{h}} \right)^T \mathbf{h} \quad (29)$$

$$c_{ijkl}|_{\epsilon \rightarrow 0, \mathbf{F} \rightarrow 0} = \frac{1}{V} \left[ \left( \frac{\partial \epsilon_{ij}}{\partial \mathbf{h}} \right)^T \mathbf{h} \right]_{kl} \quad (30)$$

where  $V$  is the volume,  $\epsilon$  is the  $3 \times 3$  virial stress tensor,  $\mathbf{h}$  is the *row-major*  $3 \times 3$  lattice tensor,  $\mathbf{F}$  and  $\mathbf{R}$  are

FIG. 2. The architecture of TensorAlloy.

$N \times 3$  matrices representing the total forces and atomic positions.

In this work, the loss  $\mathbf{L}^{\text{elastic}}$  contributed by the elastic tensor is also measured by the RMSE between  $c_{ijkl}$  and  $c_{ijkl}^{\text{dft}}$ :

$$\mathbf{L}^{\text{elastic}} = \sum_{\Omega} (\omega_{\Omega} \cdot \mathbf{RMSE}_{\Omega} + \|\epsilon\| + \|\mathbf{F}\|) \quad (31)$$

$$\omega_{\Omega} = \mathbf{ReLU}(\mathbf{MAE}_{\Omega} - \tau) \quad (32)$$

$$\mathbf{ReLU}(x) = \begin{cases} x & x \geq 0 \\ 0 & x < 0 \end{cases} \quad (33)$$

where  $\sum_{\Omega}$  loops through all included crystals,  $\mathbf{MAE}_{\Omega}$  and  $\mathbf{RMSE}_{\Omega}$  are the mean absolute error and root mean squared error between predicted elastic constants and DFT elastic constants.  $\tau$  is a pre-selected gate parameter. When  $\mathbf{MAE}$  is below  $\tau$ ,  $\mathbf{L}^{\text{elastic}}$  will not contribute to the total loss. In this work,  $\tau$  is set to 2 GPa.

The adoption of physical constraints in optimizing MLIPs can be very helpful. Without any physical constraint, adding high-quality data points is, perhaps, the only effective way to tune MLIPs for specific purposes. On the contrast, with physical constraints very few training samples are sufficient. As an example, the elementary SNAP potentials (Mo, Ni) were fitted with just hundreds of structures but they performed quite well on elastic constants and surface energies, as in the outer loop [36] of the fitting process such material properties were already used. One must also note that data consistency is important. Physical constraints are just supplementary roles in developing MLIPs, so they are preferred to be measured with first-principle calculations.

### III. IMPLEMENTATION

Fig 2 shows the architecture of the TensorAlloy program. The program has two major steps: the first step is calculating the losses of energy, force and stress terms while the second step is measuring the contributions of the physical constraints.

For the first step, the implementation is almost the same with our previous work [42] except the formula of the potential energy. The direct computation graph from atomic positions to total energy can be built because of our virtual atom approach (VAP) [42] and the vectorized

		EAM[47]	SNAP[37]	ML-EAM	ML-ADP
Energy (meV/atom)	Ni	10.6	1.2	3.9	
	Mo	58.9	13.2	23.8	18.7
Force (eV/Å)	Ni	0.06	0.05	0.05	
	Mo	0.31	0.25	0.30	0.29

TABLE I. Comparisons of the energy and force MAEs of elementary Ni and Mo.

EAM theory IIB. Hence, atomic forces and virial stress tensors can be calculated automatically thanks to the AutoGrad feature of TensorFlow. The batching scheme is adopted in this step.

For the second step, VAP also plays the key role. Only very few specific structures are needed to form physical constraints. Thus, the batching scheme is no longer a prerequisite. Instead, we use the codes of the 'prediction' phase of VAP for flexibility [42]. For each type of physical constraint and each selected crystal structure, an independent computation graph shall be generated by reusing the model parameters.

To find optimal parameters of the functions in section IIC, the overall loss function shall be defined. Just like other machine learning tasks, the mini-batch stochastic gradient descent algorithm is used to minimize the loss function. Equation 34 demonstrates the loss function used in this work:

$$\begin{aligned} \mathbf{Loss} = & \sqrt{\frac{1}{N_b} \sum_{i=1}^{N_b} (E_i - E_i^{\text{dft}})^2} \\ & + \chi_f \sqrt{\frac{1}{3 \sum_i^{N_b} N_i} \sum_i^{N_b} \sum_j^{N_i} \sum_{\alpha} (f_{ij\alpha} - f_{ij\alpha}^{\text{dft}})^2} \\ & + \chi_{\text{rose}} \mathbf{L}^{\text{Rose}} + \chi_{\text{elastic}} \mathbf{L}^{\text{elastic}} \end{aligned} \quad (34)$$

where  $N_b$  is the batch size and  $N_i$  is the number of atoms in structure  $i$ .  $\chi_f$ ,  $\chi_{\text{rose}}$  and  $\chi_{\text{elastic}}$  are overall weights of force, rose EOS and elastic contributions. The Adam optimizer [52] is used to minimize Equation 34. In most cases, we use 0.01 as the initial learning rate and the batch size ranges from 20 to 50. Since there are very few adjustable parameters compared with neural networks, the optimization typically needs very few epochs to converge. When the optimization is finished, the corresponding LAMMPS setfl potential file will be exported.

### IV. RESULTS

The public Ni-Mo dataset [37] is used to evaluate our program. This dataset is provided by Shyue Ping Ong and co-workers along with their SNAP models. It contains 3973 different Ni-Mo solids. All calculations were done by VASP [55] with the PBE [56] functional and the projector augmented-wave approach [57].

The optimized parameters are listed in the appendix.

TABLE II. Comparison of the calculated and experimental material properties of elementary fcc Ni.  $T_m$  is the melting point.  $c_{ij}$  represents elastic constants.  $E_v$  and  $E_m$  are vacancy formation energy and migration energy, respectively. SNAP refers to the elementary Ni SNAP model.

### A. Elementary Ni and Mo

We firstly use the two elementary datasets (Ni and Mo) to show our approach. These two datasets has 461 and 284 structures, respectively. 61 and 34 structures were randomly selected to form the test subsets. In these two experiments,  $\chi_f$ ,  $\chi_{\text{rose}}$  and  $\chi_{\text{elastic}}$  were set to 1, 3 and 0.05 respectively. The batch size was fixed to 25.

The original Zjw04 potentials were fitted to experimentally obtained quantities. Thus, we use the relative MAE:

$$\text{rMAE} = \frac{1}{N} \sum_{i=1}^N \left| \frac{(E_i - E_i^{\text{dft}})}{N_i} - (E_{eq} - E_{eq}^{\text{dft}}) \right| \quad (35)$$

to measure their performances. Here  $N_i$  is the number of atoms in structure  $i$ ,  $E_i$  is the Zjw04 energy of structure  $i$  while  $E_i^{\text{dft}}$  represents its corresponding DFT energy,  $E_{eq}$  and  $E_{eq}^{\text{dft}}$  refers to the equilibrium energy of Zjw04 and DFT, respectively.

Figure 3 compares the  $\rho(r)$ ,  $F(\rho)$ ,  $\phi(r)$ ,  $\mu(r)$  and  $\omega(r)$  functions. The differences between ML-EAM and ML-ADP  $\rho(r)$ ,  $\phi(r)$  and  $F(\rho)$  are quite small.

For the Ni dataset, the original Zjw04 already has a reasonable performance. The energy **rMAE** is 10.6 meV/atom and the force MAE is just 0.06 eV/Å on the entire dataset. Our machine learning approach can further enhance the performance. ML-EAM achieves 4.1 meV/atom and 0.05 eV/Å on the test set and 3.9 meV/atom and 0.05 eV/Å on the entire dataset. ML-EAM is nearly as accurate as SNAP (1.2 meV/atom, 0.05 eV/Å), but later has almost three orders of magnitude more computational expense. Figure 3 demonstrates the  $\rho(r)$ ,  $F(\rho)$  and  $\phi(r)$  functions before (Zjw04) and after machine learning optimization. The pairwise potential  $\phi(r)$  almost remains the same while the embedding function  $F(\rho)$  and the electron density function  $\rho(r)$  changes significantly. Both  $\rho(r)$  and  $\phi(r)$  converge to zero at around  $r = 4.8$  Å, which is roughly 2 times of the equilibrium spacing between nearest neighbors.

For the Mo dataset, the situation is quite different. The original Zjw04 has extremely large MAEs: the energy **rMAE** is  $\sim 59$  meV/atom and the force MAE is more than 0.31 eV/Å. Our method can significantly reduce the error: ML-EAM can achieve test MAEs of 23.8 meV/atom and 0.26 eV/Å and overall MAEs of 26.7

FIG. 4.  $\rho(r)$ ,  $F(\rho)$ ,  $\phi(r)$  of the original Zjw04 EAM, ML-EAM and ML-ADP for elementary Mo. (d) shows the  $\mu(r)$  and  $\omega(r)$  of ML-ADP.

meV/atom and 0.30 eV/\AA. We also optimized an ADP potential for this dataset. Interestingly, ML-ADP gets better results: 20.6 meV/atom and 0.24 eV/\AA on the test set and 18.7 meV/atom and 0.29 eV/\AA on the entire dataset. On the contrast, the SNAP method (13.2 meV/atom, 0.25 eV/\AA) behaves slightly better than ML-ADP. But considering the computational cost, the perfor-

FIG. 5. The energy-volume curves of the original EAM, ML-EAM and DFT for the fcc Ni.

FIG. 6. The energy-volume curves of the original EAM, ML-EAM, ML-ADP and DFT for the bcc Mo.

mance of ML-ADP is totally acceptable. Figure 4 demonstrates the potential functions. The  $\rho(r)$ ,  $F(\rho)$  and  $\phi(r)$  functions of ML-EAM and ML-ADP are quite similar. The additional accuracy of ML-ADP mainly comes from the dipole function  $\mu(r)$ .

Figure 5 and 6 plot the equation of state curves. The fitting region ranges from 84% to 118% of the corresponding equilibrium volume. For both crystals, the original EAM significantly underestimate the energy at both tensile and compress strains. However, our constrained machine learning approach can fix this problem. The energy-volume curves of ML-EAM and ML-ADP overlap with the DFT curves very well.

Table II and III summarize the predicted material properties of fcc Ni and bcc Mo, including the melting point  $T_m$ , the elastic constants ( $c_{11}$ ,  $c_{12}$  and  $c_{44}$ ), the vacancy formation energy  $E_v$ , the migration energy

TABLE III. Comparison of the calculated and experimental material properties of elementary bcc Mo. SNAP refers to the elementary SNAP Mo model.

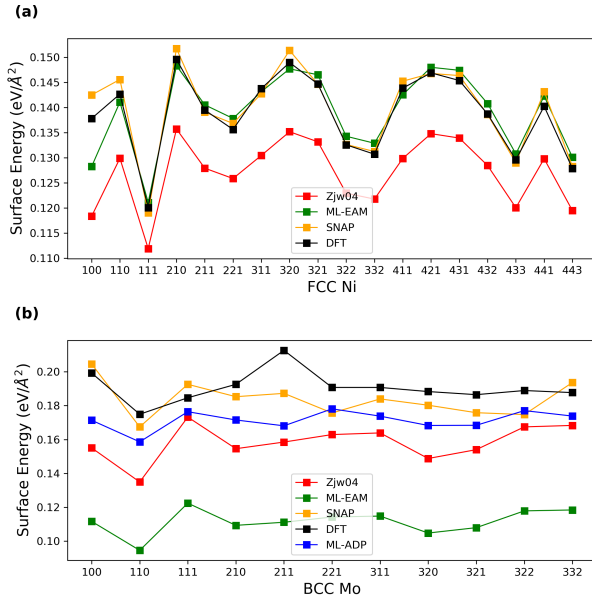

FIG. 7. Comparison of calculated surface energies of (a) fcc Ni and (b) bcc Mo.

$E_m$  and the activation energy  $E_a$ . The original Zjw04 potentials were developed by fitting material properties so they already perform well on these metrics. For the fcc Ni, the machine-learned EAM has gained better performances on predicting elastic constants. For the bcc Mo, ML-ADP not only gives quality predictions on elastic properties but also significantly reduces the error of predicting  $E_m$ . We also tested these models with surface energy, as shown in Fig 7. One must note that all the slab structures are relaxed independently with corresponding potentials. For the fcc Ni, ML-EAM can give almost exactly the same results with DFT. For the more complicated bcc Mo, the central-force ML-EAM model becomes not that good due to the lacking of directional bonding [14]. The angular correction, introduced by Mishin, shows its importance. ML-ADP can give com-

parable results to the SNAP method.

We further examined our ML-EAM and ML-ADP by calculating the melting temperature of fcc Ni and bcc Mo using the solid-liquid coexistence approach. For fcc Ni,  $30 \times 10 \times 10$  supercells were used and for bcc the supercells  $30 \times 15 \times 15$  were used. The time step was set to 1 fs. The simulation for each temperature was carried out for at least 300 ps. For fcc Ni,  $T_m$  remains the same for ML-EAM, 200 K lower than the experiment  $T_m$ . However, the calculated  $T_m$  of Mo is greatly improved. The original Zjw04  $T_m$  is around 3750 K, 800 K higher than experiment (2890 K) while both ML-EAM and ML-ADP can give quite accurate melting temperature.

## B. Mo-Ni

Secondly, we tested our method on the entire binary Mo-Ni dataset. 300 structures were randomly chosen to be the test dataset and the rest 3673 were used to train the potentials.  $\chi_f$ ,  $\chi_{\text{rose}}$  and  $\chi_{\text{elastic}}$  were set to 1, 1 and 0.05 respectively. The batch size was increased to 50. Only the equilibrium fcc Ni and bcc Mo are included in  $\Omega$  of Equation 31 and 28.

The original EAM uses a simplified combined form to describe the pairwise interaction of A-B (Equation 17). However, we did a minor modification: by adding more fitting parameters we use Equation 16 directly. Thus, in total, there are 44 learnable parameters for ML-EAM and 68 for ML-ADP. One should note that in this section, SNAP, ML-EAM and ML-ADP all refer to their corresponding binary form.

Table IV summarizes the energy and force MAEs of SNAP, ML-EAM and ML-ADP on the different subsets. ML-ADP becomes the overallly best. Both the energy MAE (19.6 meV/atom) and the force MAE (0.20 eV/Å) are smaller than those of the binary SNAP (22.5 meV/atom and 0.23 eV/Å). The pure Mo is still a challenge for ML-ADP as the energy and force MAEs are noticeably large but still much smaller than the original Zjw04 EAM. The binary SNAP predicts well on pure Ni

FIG. 8. Energy-volume curves of  $\text{Ni}_3\text{Mo}$  and  $\text{Ni}_4\text{Mo}$  obtained with the original Zjw04 EAM, ML-EAM, ML-ADP, SNAP and DFT.

and Mo. But ML-ADP outperforms the SNAP model on binary phases ( $\text{Ni}_3\text{Mo}$ , Ni-doped Mo and especially the Mo-doped Ni). On the contrast, ML-EAM still performs significantly worse compared with ML-ADP due to the restriction of the central-force model, as discussed before. Interestingly, our results suggest that Mo-Ni dipole and quadrupole contributions are completely negligible (Figure S1 in the appendix). The Ni-Ni dipole and quadrupole interactions are an order of magnitude weaker than those of Mo-Mo.

Figure 8 demonstrates the energy-volume curves of  $\text{Ni}_3\text{Mo}$  and  $\text{Ni}_4\text{Mo}$ . The original Zjw04 EAM can not properly describe the energy-volume relations of these two crystals in wide range. The ML-ADP curves agrees perfectly with the DFT curves. ML-EAM agrees well under tensile strains but overestimates the energy under compress strains.

Table V summarizes the elastic constants predictions of  $\text{Ni}_3\text{Mo}$  and  $\text{Ni}_4\text{Mo}$ . One should note that these two crystals were not included in the  $\Omega$  of Equation 31 and 28 but their elastic properties were used to tune the binary SNAP model. The original Zjw04 EAM performs obviously poorly on predicting elastic constants. Some absolute percentage errors can even exceed 100%. With our machine learning correction, ML-EAM, especially ML-ADP, can give much more accurate predictions. For the  $\text{Ni}_3\text{Mo}$  crystal, the average absolute percentage error is reduced from 40% (Zjw04) to 20% (ML-ADP). ML-ADP even beats SNAP on 4 ( $c_{11}$ ,  $c_{12}$ ,  $c_{22}$  and  $c_3$ ) of the 7 elastic metrics. For the  $\text{Ni}_4\text{Mo}$  crystal, the average absolute percentage error is also decreased.

### C. Discussions

The above results suggest that with machine learning and essential physical constraints, for the fcc and bcc solids, the traditional empirical potentials, EAM/ADP, can be improved to be almost as accurate as the SNAP method using exactly the same dataset. But, EAM/ADP are around  $10^2$  to  $10^3$  times faster than SNAP. To understand this, we can start from the many-body expansion (MBE) scheme [60].

MBE is one of the most widely used schemes for fitting potential energy surfaces. In the many-body expansion scheme, the total energy of a system with  $N$  atoms can be expressed as the sum of all  $k$ -body terms where  $k \leq N$ :

$$E = \sum_i C_1^N E_i^{(1)} + \sum_{i,j} C_2^N E_{ij}^{(2)} + \sum_{i,j,k} C_3^N E_{ijk}^{(3)} + \dots \quad (36)$$

where  $C_k^N$  ( $k=1,2,3$ ) is the binomial coefficient and  $E^{(k)}$  represents the  $k$ -body contribution. In many cases, higher-order terms like  $E_{ij}$  or  $E_{ijk}$  are symmetric:  $E_{ij} = E_{ji}$ ,  $E_{ijk} = E_{ikj} = E_{jik} = \dots$ . Thus, Equation 36 can be further transformed to:

$$E = \sum_i^N \left( E_i^{(1)} + \frac{1}{2!} \sum_{j \neq i}^N E_{ij}^{(2)} + \frac{1}{3!} \sum_{j \neq i}^N \sum_{k \neq i,j}^N E_{ijk}^{(3)} + \dots \right) = \sum_i^N E_i \quad (37)$$

where  $E_i$  is the atomic energy of atom  $i$ .

In fact, both the EAM and the SNAP formalisms can be considered as variants of MBE. For the EAM method,

	Model	Mo	Ni <sub>4</sub> Mo	Ni <sub>3</sub> Mo	MoNi	NiMo	Ni	Overall
Energy (meV/atom)	SNAP [37]	16.2	4.0	5.2	22.7	33.9	7.9	22.5
	ML-EAM	30.4	11.1	8.6	29.8	33.9	11.6	26.2

TABLE V. Comparison of elastic constants ( $c_{ij}$ , GPa), Voigt-Reuss-Hill bulk modulus ( $B_{\text{VRH}}$ , GPa), Voigt-Reuss-Hill shear modulus ( $G_{\text{VRH}}$ , GPa) and homogeneous Poisson's ratio ( $\mu$ ) for fcc Ni, bcc Mo and binary alloys Ni<sub>3</sub>Mo and Ni<sub>4</sub>Mo.

the embedding contribution  $F(\rho)$  serves as a "special" one-body term because the many-body effect is considered. The overall pairwise contribution  $\frac{1}{2} \sum_{j \neq i} \phi(r_{ij})$  is just a plain transcription of the two-body term in Equation 37. For the SNAP method, the atomic energy is calculated with the following equation:

$$E_i = \beta_0^{\alpha_i} + \sum_k \beta_k^{\alpha_i} B_k^i \quad (38)$$

where  $\beta_0^{\alpha_i}$  and  $\beta_k^{\alpha_i}$  are learnable scalar parameters,  $\alpha_i$  indicates the element type of atom  $i$ .  $B_k^i$  is a bispectrum coefficient. The calculation of  $B_k^i$  is very complicated [35] but it is still a two-body term. The overall two-body contribution is a linear combination of  $B_k^i$ . Thus, the SNAP formalism can be viewed as an assemble of a simplified one-body term with a complicated two-body term. On the other hand, the EAM formalism is built up with a 'complicated' one-body term and a rather simple

two-body term. The central-force EAM works well on fcc metals. For bcc metals with partially filled d bands, the directional d bonding cannot be ignored. Hence, the pairwise dipole and quadrupole functions introduced by ADP are necessary.

As we analysed in Section II B, the fundamental atomic descriptor of EAM, the  $N \times N^{\text{nl}} \times 4$  matrix  $\mathbf{G}$ , is composed of just raw interatomic distances. However, interatomic distances alone may not uniquely describe a structure. To avoid this problem, the cutoff was raised up to 6.5 Å. As a comparison, the overall  $r_{\text{cut}}$  for the binary SNAP is 4.6 Å. But such descriptor is still too rough to describe complicated potential energy surfaces (e.g. bcc Mo). To further enhance EAM/ADP, complicated three-atoms interactions may be necessary.

## V. CONCLUSIONS

To conclude, we have successfully combined empirical potentials (EAM/ADP) with machine learning. The machine learning approaches (big data, optimization, etc), together with physical constraints (Rose EOS, elastic constants) can significantly improve the performances of EAM/ADP. For the fcc Ni, bcc Mo and Mo-Ni alloys, ML-EAM and ML-ADP can be as accurate as SNAP, while later method is orders of magnitude slower. Our work also indicates a new route to design and develop machine learning interatomic potentials —the machine learning enhanced empirical potential approach.

## DATA AVAILABILITY

The optimized parameters of the associated EAM and ADP models are all listed in the appendix. The learning datasets are originally created by Shyue Ping Ong and can be accessed from GitHub freely.
